We summarize three recent efforts to constrain the first few moments of cosmic creation before and during the epoch of inflation. We consider two means to explain a slight dip in the power spectrum of the cosmic microwave background for multipoles in the range of $\ell = 10 - 30$ from both the *Planck* and *WMAP* data. We show that such a dip could be the result of resonant creation of a massive particle that couples to the inflaton field. For best-fit models, the epoch of resonant particle creation reenters the horizon at wave numbers of $k_* \sim 0.00011 \pm 0.0004$ ($h \text{ Mpc}^{-1}$). The amplitude and location of these features correspond to the creation of a number of degenerate fermion species of mass $\sim 15/\lambda^{3/2} m_{pl}$ during inflation where λ is the coupling constant between the inflaton field and the created fermion species. Alternatively, one can explain the existence of such a dip as due to a jump in the inflation generating potential. We show that such a jump can also resolve the excessively large dark flow predicted from the M-theory landscape. Finally, we summarize our efforts to quantify constraints on the cosmic dark flow from a new analysis of the Type Ia supernova distance-redshift relation.

Keywords: Cosmic microwave background; Cosmological inflation; Dark flow.

1. Introduction

Analysis^{1,2} of the power spectrum of fluctuations in the cosmic microwave background (CMB) provides powerful constraints on the physics of the very early universe. The most popular account for the origin of the primordial power spectrum is based upon quantum fluctuations generated during the inflationary epoch.^{3,4} Subsequently, acoustic oscillations of the photon-baryon fluid distort this to produce the observed features in the angular power spectrum of temperature fluctuations in the CMB and the spatial power spectrum of matter density fluctuations.

In this context, there now exists the highest resolution yet available in the determination of the power spectrum of the CMB from the *Planck* Satellite.^{1,2} In Mathews et al.⁵ we made note of a peculiar feature visible in the power spectrum near multipoles $\ell = 10 - 30$. This is an interesting region in the CMB power spectrum because it corresponds to angular scales that are not yet in causal contact, so that the observed power spectrum is close to the true primordial power spectrum.

An illustration of the *Planck* observed power spectrum in this region is visible on Figure 1 from Mathews et al.⁵ Although the error bars are large, there is a noticeable systematic deviation in the range $\ell = 10 - 30$ below the best fit based upon the standard Λ CDM cosmology with a power-law primordial power spectrum. This same feature is visible in the CMB power spectrum from the Wilkinson Microwave Anisotropy Probe (*WMAP*),⁶ and hence, is likely a true feature in the CMB power spectrum. This can be interpreted as an artifact of the cosmic variance,¹ or a phase transition in the inflation-generating potential.⁷⁻⁹ However, here we adopt the premise that this could be a real feature in the primordial power spectrum produced by new trans-Planckian physics occurring near the end of the inflation epoch. In particular, we show that this feature is well represented by the resonant creation^{10,11} of Planck-scale particles that couple to the inflaton field as shown by the solid line in Figure 1 and we now describe in detail.

This interpretation has the intriguing aspect that, if correct, an opportunity emerges to use the CMB as a probe of physics at the Planck scale ($m_{pl} \sim 10^{19}$ GeV). Indeed, massive particles generically exist in Planck scale compactification schemes of string theory from the Kaluza-Klein states, winding modes, and the massive (excited) string modes. We have explored⁵ the possibility that the mass of some Planck-scale particles lies in the range of the vacuum energy associated with the last 9-10 e -folds of inflaton accessible to observation.

2. Inflation Resonant Particle Production

The details of the resonant particle creation paradigm have been explained in Refs. 5, 10, 11. Here, we summarize essential features. In the basic inflationary picture, a rapid early expansion of the universe is achieved through the vacuum energy from an inflaton field. In the minimal extension from the basic picture considered here, the inflaton is postulated to couple to massive particles whose mass is of order the inflaton field value. These particles are then resonantly produced as the field

Fig. 1. CMB power spectrum in the range of $\ell = 0 - 50$ from Mathews et al.⁵ Points with error bars are from the *Planck* Data Release.¹ The dashed line shows the best standard Λ CDM fit to the *Planck* CMB power spectrum based upon a power-law primordial power spectrum. The solid line shows the best fit for a model with resonant particle creation during inflation.

obtains a critical value during inflation. If even a small fraction of the inflaton field is affected in this way, it can produce an observable feature in the primordial power spectrum. In particular, there can be either an excess,^{10,11} or a dip⁵ in the power spectrum. Such a dip, will occur at an angular scale corresponding to when the epoch of resonant particle creation crossed the Hubble radius during inflation.

We note that particle creation corresponding to an imaginary part of the effective action of quantum fields has been considered in.¹² In that case the same creation should occur at the present time. In that case compatibility with the diffuse γ -ray background can be used to rule out the possibility of measurable effects from this type of trans-Planckian particle creation in the CMB anisotropy. However, the effect of interest here is a perturbation in the simple scalar field due to direct coupling to Planck-mass particles at energies for which the inflation potential is comparable to the particle mass and cannot occur at the present time. The present scenario, therefore is not constrained by the diffuse gamma-ray background.

In the simplest slow roll approximation^{3,4} for the generation of density perturbations during inflation, the amplitude, $\delta_H(k)$, of a density fluctuation when it crosses the Hubble radius is just,

$$\delta_H(k) \approx \frac{H^2}{5\pi\dot{\phi}}, \quad (1)$$

where H is the expansion rate, and $\dot{\phi}$ is the rate of change of the inflaton field when the comoving wave number k crosses the Hubble radius during inflation. If resonant particle production affects the inflaton field, then the conjugate momentum in the field $\dot{\phi}$ is altered. This causes either an increase or a diminution in $\delta_H(k)$ (the

4 *Mathews et al.*

primordial power spectrum) for those wave numbers which exit the horizon during the resonant particle production epoch.

For the application here, we adopt a positive Yukawa coupling of strength λ between the inflaton field ϕ and the field ψ of N fermion species. This differs from^{10,11} who adopted a negative Yukawa coupling. With our choice, the total lagrangian density including the inflaton scalar field ϕ , the dirac fermion field, and the Yukawa coupling term is then written,

$$\mathcal{L}_{\text{tot}} = \frac{1}{2} \partial_\mu \phi \partial^\mu \phi - V(\phi) + i \bar{\psi} \gamma^\mu \psi - m \bar{\psi} \psi + N \lambda \phi \bar{\psi} \psi \quad . \quad (2)$$

For this Lagrangian, it is obvious that the fermions have an effective mass of

$$M(\phi) = m - N \lambda \phi \quad . \quad (3)$$

This vanishes for a critical value of the inflaton field, $\phi_* = m/N\lambda$. Resonant fermion production will then occur in a narrow range of inflaton field amplitude around $\phi = \phi_*$.

As in Refs. 5, 10, 11 we label the epoch at which particles are created by an asterisk. So the cosmic scale factor is labeled a_* at the time t_* at which resonant particle production occurs. Considering a small interval around this epoch, one can treat $H = H_*$ as approximately constant (slow roll inflation). The number density n of particles can be taken as zero before t_* and afterwards as $n = n_* [a_*/a(t)]^3$. The fermion vacuum expectation value can then be written,

$$\langle \bar{\psi} \psi \rangle = n_* \Theta(t - t_*) \exp[-3H_*(t - t_*)] \quad . \quad (4)$$

where Θ is a step function.

Then following the previous derivations,^{5,10,11} we have the following modified equation of motion for the scalar field coupled to ψ :

$$\ddot{\phi} + 3H\dot{\phi} = -V'(\phi) + N\lambda \langle \bar{\psi} \psi \rangle \quad , \quad (5)$$

where $V'(\phi) = dV/d\phi$. In the slow roll approximation, ($\ddot{\phi} \sim 0$, $H \sim H_*$, $V'(\phi) \sim V'(\phi_*)$) this differential equation after particle creation ($t > t_*$) is then the same as in^{10,11} but with a sign change for the coupling term, i.e.

$$\begin{aligned} \dot{\phi}(t > t_*) &= \dot{\phi}_* \exp[-3H(t - t_*)] \\ &\quad - \frac{V'(\phi)_*}{3H_*} [1 - \exp[-3H(t - t_*)]] \\ &\quad + \frac{N\lambda}{3H_*} n_*(t - t_*) \exp[-3H_*(t - t_*)] \quad . \end{aligned} \quad (6)$$

The physical interpretation here is that the rate of change of the scalar field rapidly increases due to the coupling to particles created at the resonance $\phi = \phi_*$.

Then, using Eq. (1) for the fluctuation as it exits the horizon, and constant $H \approx H_*$ in the slow-roll condition along with

$$d \ln a = H dt \quad , \quad (7)$$

one obtains the perturbation in the primordial power spectrum as it exits the horizon:

$$\delta_H = \frac{[\delta_H(a)]_{N\lambda=0}}{1 + \Theta(a - a_*)(N\lambda n_*/|\dot{\phi}_*|H_*)(a_*/a)^3 \ln(a/a_*)} . \quad (8)$$

Here, it is clear that the power in the fluctuation of the inflaton field will diminish as the particles are resonantly created when the universe grows to some critical scale factor a_* .

Using $k_*/k = a_*/a$, the perturbation spectrum Eq. (8) can be reduced^{5,11} to a simple two-parameter function.

$$\delta_H(k) = \frac{[\delta_H(a)]_{N\lambda=0}}{1 + \Theta(k - k_*)A(k_*/k)^3 \ln(k/k_*)} . \quad (9)$$

where the amplitude A and characteristic wave number k_* ($k/k_* \geq 1$) can be fit to the observed power spectra from the relation:

$$k_* = \frac{\ell_*}{r_{lss}} , \quad (10)$$

where r_{lss} is the comoving distance to the last scattering surface, taken here to be 14 Gpc.

The connection between resonant particle creation and the CMB temperature fluctuations is straightforward. As usual, temperature fluctuations are expanded in spherical harmonics, $\delta T/T = \sum_l \sum_m a_{lm} Y_{lm}(\theta, \phi)$ ($2 \leq l < \infty$ and $-l \leq m \leq l$). The anisotropies are then described by the angular power spectrum, $C_l = \langle |a_{lm}|^2 \rangle$, as a function of multipole number l . One then merely requires the conversion from perturbation spectrum $\delta_H(k)$ to angular power spectrum C_l . This is easily accomplished using the *CAMB* code.¹³ When converting to the angular power spectrum, the amplitude of the narrow particle creation feature in $\delta_H(k)$ is spread over many values of ℓ . Hence, the particle creation feature looks like a broad dip in the power spectrum.

We have made a multi-dimensional Markov Chain Monte-Carlo analysis^{14,15} of the CMB using the *Planck* data¹ and the *CosmoMC* code.¹⁵ For simplicity and speed in the present study we only marginalized over parameters which do not alter the matter or CMB transfer functions. Hence, we only varied A and k_* , along with the six parameters, $\Omega_b h^2, \Omega_c h^2, \theta, \tau, n_s, A_s$. Here, Ω_b is the baryon content, Ω_c is the cold dark matter content, θ is the acoustic peak angular scale, τ is the optical depth, n_s is the power-law spectral index, and A_s is the normalization. As usual, both n_s and A_s are normalized at $k = 0.05 \text{ Mpc}^{-1}$.

Figure 2 shows contours of likelihood for the resonant particle creation parameters, A and k_* . Adding this perturbation to the primordial power spectrum improves the total χ^2 for the fit from 9803 to 9798. One expects that the effect of interest here would only make a small change ($\Delta\chi^2 = 5$) in the overall fit because it only affects a limited range of l values. Nevertheless, from the likelihood contours we can deduce mean value of $A = 1.7 \pm 1.5$ with a maximum likelihood value of $A = 1.5$, and a mean value of $k_* = 0.0011 \pm 0.0004 \text{ h Mpc}^{-1}$.

Fig. 2. Constraints on parameters A and k_* from the MCMC analysis⁵ of the CMB power spectrum. Contours show 1 and 2σ limits. The horizontal axis is in units of $(h \text{ Mpc}^{-1})$.

The values of A and k_* determined from the CMB power spectrum relate to the inflaton coupling λ and fermion mass m , for a given inflation model via Eqs. (8) and (9).

$$A = |\dot{\phi}_*|^{-1} N \lambda n_* H_*^{-1} \quad (11)$$

The coefficient A can be related directly to the coupling constant λ using the approximation^{10,16–18} for the particle production Bogoliubov coefficient

$$|\beta_k|^2 = \exp\left(\frac{-\pi k^2}{a_*^2 N \lambda |\dot{\phi}_*|}\right). \quad (12)$$

Then,

$$n_* = \frac{2}{\pi^2} \int_0^\infty dk_p k_p^2 |\beta_k|^2 = \frac{N \lambda^{3/2}}{2\pi^3} |\dot{\phi}_*|^{3/2}. \quad (13)$$

This gives

$$A = \frac{N \lambda^{5/2}}{2\pi^3} \frac{\sqrt{|\dot{\phi}_*|}}{H_*} \quad (14)$$

$$\approx \frac{N \lambda^{5/2}}{2\sqrt{5}\pi^{7/2}} \frac{1}{\sqrt{\delta_H(k_*)|_{\lambda=0}}}, \quad (15)$$

where we have used the usual approximation for the primordial slow roll inflationary spectrum.^{3,4} This means that regardless of the exact nature of the inflationary scenario, for any fixed inflationary spectrum $\delta_H(k)|_{\lambda=0}$ without the back reaction, we have the particle production giving a dip of the form Eq. (9) with the parameter

A expressed in terms of the coupling constant through Eq. (15). Given that the CMB normalization requires $\delta_H(k)|_{\lambda=0} \sim 10^{-5}$, we then have

$$A \sim 1.3N\lambda^{5/2}. \quad (16)$$

Hence, for the maximum likelihood value of $A \sim 1.5$, we have

$$N \approx \frac{(1.1^{+1.1}_{-0.9})}{\lambda^{5/2}} \sim \frac{1}{\lambda^{5/2}}. \quad (17)$$

So, $\lambda \leq 1$ requires $N > 1$ as expected.

The fermion particle mass m can then be deduced from $m = N\lambda\phi_*$. From Eq. (17) then we have $m \approx \phi_*/\lambda^{3/2}$. For this purpose, however, one must adopt a specific form for the inflaton potential to determine ϕ_* appropriate to the scale k_* . Here we adopt a general monomial potential whereby:

$$V(\phi) = \Lambda_\phi m_{pl}^4 \left(\frac{\phi}{m_{pl}} \right)^\alpha, \quad (18)$$

for which there is a simple analytic relation³ between the value of ϕ_* and the number of e-folds $\mathcal{N}(k_*)$ between when k_* exits the horizon and the end of inflation, i.e.

$$\mathcal{N}(k_*) = \frac{1}{m_{pl}^2} \int_{\phi_{end}}^{\phi_*} \frac{V(\phi)}{V'(\phi)} d\phi, \quad (19)$$

implies

$$\phi_* = \sqrt{2\alpha\mathcal{N}} m_{pl}. \quad (20)$$

For $k_* = 0.0011 \pm 0.0004 h \text{ Mpc}^{-1}$, and $k_H = a_0 H_0 = (h/3000) \text{ Mpc}^{-1} \sim 0.0002$, we have $\mathcal{N} - \mathcal{N}_* = \ln(k_H/k_*) < 1$. Typically one expects $\mathcal{N}(k_*) \sim \mathcal{N} \sim 50$ although one can have the number of e-folds as low as $\mathcal{N} \sim 25$ in the case of thermal inflation.³ So, for a monomial potential with $\alpha = 2$ we have $\phi_* \sim 10 - 14 m_{pl}$. On the other hand, the limits on the tensor to scalar ration from the *Planck* analysis² are more consistent with $\alpha = 1$ ($\phi_* = 7 - 10 m_{pl}$), or even $\alpha = 2/3$ ($\phi_* = 6 - 8 m_{pl}$). Hence, we have roughly the constraint,

$$m \sim 6 - 14 \frac{m_{pl}}{\lambda^{3/2}}, \quad (21)$$

well in excess of the Planck mass and independently of the number of degenerate species.

As noted above, it is natural¹⁰ to have such trans-Planckian massive particle in numerous extensions of the Standard Model such as supergravity and superstring theories. Such extra-dimensional theories generally contain a spectrum of particles with masses well in excess of the Planck mass. The extra-dimensions are compact and smaller than the three large spatial dimensions. It is, therefore, possible to dimensionally reduce the system to obtain an effective (3+1) dimensional theory that produces a tower of Kaluza-Klein (KK) states.^{19,20} The mass of states in this tower is of order of the inverse size of the extra dimension. Since the extra dimensions are expected to have a size characteristic of the Planck length, these

KK states therefore have masses in excess of the Planck masses. Furthermore, these KK states can be nearly degenerate, with the level of degeneracy depending upon the geometrical structure of the compact space. It is, therefore, natural to deduce that a large number of nearly degenerate fermions existed during inflation with a mass well in excess of m_{pl} , and that these particles couple to the inflaton field that drives inflation. For our purposes this degeneracy factor is described by the parameter N , and in such theories N can easily be of the order of 100. Hence, such a detectable signature in the CMB power is not unexpected.

3. Matter Power Spectrum

It is straight forward to determine the matter power spectrum. To convert the amplitude of the perturbation as each wave number k enters the horizon, $\delta_H(k)$, to the present-day power spectrum, $P(k)$, which describes the amplitude of the fluctuation at a fixed time, one must make use of a transfer function, $T(k)$ ²¹ which is easily computed using the *CAMB* code¹³ for various sets of cosmological parameters (e.g. Ω , H_0 , Λ , Ω_B). An adequate approximate expression for the structure power spectrum is

$$\frac{k^3}{2\pi^2}P(k) = \left(\frac{k}{aH_0}\right)^4 T^2(k)\delta_H^2(k) . \quad (22)$$

This expression is only valid in the linear regime, which in comoving wave number is up to approximately $k \lesssim 0.2 \, h \, \text{Mpc}^{-1}$ and therefore adequate for our purposes. However, we also correct for the nonlinear evolution of the power spectrum.²²

Figure 3 shows the matter power spectrum from the *Wiggle-Z Dark Energy Survey*²³ compared to the computed maximum likelihood power spectrum with and without the perturbation due to the resonant particle creation. Unfortunately, the perturbation is on a scale too large to be probed by the observed matter power spectrum.

4. Low Velocity Cosmic Dark Flow and the CMB power spectrum

An alternative way to explain the dip for $\ell = 10 - 30$ has been pointed out by a number of authors^{2,7} as due to an abrupt jump in the inflation-generating potential. In normal slow roll inflation,

$$\dot{\phi} = \frac{dV(\phi)/d\phi}{3H} , \quad (23)$$

Hence, a large value for $dV(\phi)/d\phi$ can also produce a jump in the primordial power spectrum of Eq. 1. In Gangopadhyay and Mathews⁸ we have explored this possibility with a potential of the form

$$V(\varphi) = \frac{1}{2}m\varphi^2 + \lambda M_{Pl}^4 \exp [(-\varphi/\varphi_1)^\alpha] , \quad (24)$$

Fig. 3. Comparison of the observed galaxy cluster function from²³ with the spectrum implied from the fits to the matter power spectrum with (solid line) and without (dashed line) resonant particle creation during inflation from Ref. 5.

where, α is any odd number, but we adopt to $\alpha \leq 3$ to ensure the renormalizability. The parameter φ_1 then fixes the dip in the potential.⁸ For appropriate values of the potential parameters, a fit very similar to that of Figure 1 is attainable.

4.1. Potential break and cosmic dark flow

The particular relevance of our work,⁸ however, is that a break in the inflation-generating potential not only explains the dip, but resolves another problem in early-universe cosmology, namely the magnitude of cosmic dark flow predicted in the M-theory landscape.^{24–27}

The string landscape²⁴ is a complex space of a huge number of string vacua. These vacua differ from one another due to the complexity of RR fluxes and whether they are included or not and also the appearance of the gauge groups in the lower energy scale. A full analysis of the structure of the landscape is beyond the scope of present physics. However, there should be at least 10^{500} to 10^{600} possible vacua points in the landscape.²⁸ Starting from this, a model for the landscape was constructed^{25–27} as a lattice of vacua with a distribution of lattice energies. This landscape lattice-like structure has two sectors SUSY and non-SUSY. Localization disconnects these two sectors, while in the SUSY sector the landscape is viewed as a regular lattice, the non-SUSY sector exhibits an Anderson localization around each vacua site. Accepting that Supersymmetry is a broken symmetry, then the vacuum energy densities can vary widely being positive, negative or zero.

All landscape vacua have equal probability to give birth to a universe. It has been shown in Refs. 25–27 that there are two kinds of baby universes: one kind will survive the back reaction due to quantum gravitational effects; and the other will be

terminal universes that will not survive the back reaction. Since all of the surviving universes were casually connected initially due to quantum unitarity, there will be an entanglement among all survivors. This entanglement should be imprinted in our survivor universe as well.

4.2. *Modified Friedmann Equation*

In the landscape scenario one must include the back-reaction due to the quantum entanglement with super horizon size wavelength modes.^{25–27} Then, the modified Friedmann equation becomes:

$$H^2 = \frac{1}{3M_P^2} [V(\varphi) + \frac{1}{2} (\frac{V(\varphi)}{3M_P^2})^2 F(b, V)] \equiv \frac{V_{eff}}{3M_P^2} , \quad (25)$$

where,

$$F(b, V) = \frac{3}{2} (2 + \frac{m^2 M_P^2}{V}) \log(\frac{b^2 M_P^2}{V}) - \frac{1}{2} (1 + \frac{m^2}{b^2}) \exp(-3 \frac{b^2 M_P^2}{V}) . \quad (26)$$

Here, M_P^2 is $8\pi G_N$, $V(\varphi)$ is the inflation potential, b is the SUSY breaking scale and $m^2 = V(\phi)''$. The interference length is given by:

$$L_1^2 = \frac{a}{H} [(\frac{m^2}{3H}) \ln \frac{b}{H} - \frac{m^2 H}{6} (\frac{1}{b^2} - \frac{1}{H^2})] . \quad (27)$$

4.3. *'Tilting' gravitational potential*

The length scale L_1 characterized the superhorizon size inhomogeneties. This non-local entanglement leads to a modification term $\delta\Phi$ added to the gravitational potential.

$$\Phi = \Phi^0 + \delta\Phi \simeq \Phi^0 [1 + \frac{V(\varphi)F(b, V)}{3M_P^2} (\frac{r}{L_1})] \quad (28)$$

where Φ^0 is the inflationary standard gravitational potential and $\delta\Phi$ is the 'tilt'. This tilt in the potential is responsible for the dark flow.^{25–27}

For the quadruple anisotropy we get²⁷

$$\frac{\Delta T}{T}|_{quad} \simeq 0.5 (\frac{r_h}{L_1})^2 (\frac{V(\varphi)F(b, V)}{18M_P^2}) \quad (29)$$

Similarly, the effect on anisotropy for dipole is:²⁷

$$\frac{\Delta T}{T}|_{dip} \simeq \frac{4\pi}{15} (\frac{r_h}{L_1}) (\frac{V(\varphi)F(b, V)}{18M_P^2}) \quad (30)$$

The dark flow velocity (alid for $L_1 \gg r_H$) is then^{25–27}

$$\beta = \frac{v}{c} \simeq \alpha (\frac{\Delta T}{T})|_{dip} \simeq \frac{4\pi}{15} (\frac{r_h}{L_1}) (\frac{V(\varphi)F(b, V)}{18M_P^2}) \quad (31)$$

Fig. 4. Dark velocity vs z plot with $b \simeq 10^{-10} M_P$

Where we have used 100 km s^{-1} for each $0.4 \mu K$ anisotropy in converting the dipole temperature as in Ref. 27.

We have revised⁸ the theory of Refs.^{25–27} for a generic inflaton potential and applied it to the specific "break" potential described above in Eq. (24). Changing the inflaton potential to the new potential in Eq. (24) modifies the form of the correction term $F(b, V)$. Since the limits on the SUSY breaking scale are quite stringent, $10^{-10} M_P \leq b \leq 10^{-8} M_P$, the change in the modification mainly comes from the fact the inflaton potential is chaotic-like. This is an interesting case as most of the other possible potentials give much higher dark-flow velocity.

In Figure 4 from Ref. 8 one can see the dark flow vs. redshift z for SUSY scale $b \simeq 10^{-10} M_P$. This energy scale can be tested in the distant future in the proposed ILC. If we go to a higher breaking scale we get a higher value for dark flow.

In Refs. 25–27 a SUGRA like potential was employed of the form:

$$V(\varphi) = V_0 \exp\left(-\lambda \frac{\varphi}{M_P}\right) . \quad (32)$$

Using this potential a 'dark' flow of the order of $650\text{--}750 \text{ km s}^{-1}$ was obtained. In Ref. 8 we have repeated the calculations of Refs. 25–27, but with with the jump potential of Eq. (24). Adopting our model the resultant dark flow velocity diminishes considerably is illustrated in Figure 4.

5. Observational Constraints on Dark Flow

The above analysis of a lower landscape-generated dark flow velocity is of interest because there are now significant constraints on the bulk flow velocity. In Mathews et al.²⁹ we have summarized recent constraints on the dark (or bulk) flow velocity, and completed a new analysis based upon an analysis of the SNIa redshift-distance relation. We made two analyses: one identifying the three dimensional Cartesian

velocity components; the other analyzing the cosine dependence on the sky of the deviation from Hubble flow. Fits were for $z < 0.05$ and $z > 0.05$ using both the Union2.1 and SDSS-II supernova surveys. We also studied²⁹ simulated data in which a bulk flow was imposed to determine whether the difficulty in detecting a bulk flow at high redshift is due to uncertainty in the redshift-distance relation, confusion with peculiar velocities, or the absence of a bulk flow. We found²⁹ a bulk flow velocity of $270 \pm 30 \text{ km s}^{-1}$ in the direction $(l, b) = (295 \pm 30, 10 \pm 5)^\circ$ in the Cartesian analysis, while the cosine analysis gave $325 \pm 50 \text{ km s}^{-1}$ in the direction $(l, b) = (276 \pm 15, 37 \pm 3)^\circ$, consistent with previous analyses. In the redshift bin $z > 0.05$, however, we found²⁹ only marginal evidence for a bulk flow velocity. We also found that the SDSS-II supernova data set has insufficient sky coverage to provide a meaningful result.

The current observational situation is summarized in Ref. 29 as follows: it has been known since the 1980's³⁰ that the local dipole flow extends well beyond the local super-cluster. This source was dubbed “the Great Attractor.” However, subsequent work in the 1990's³¹ has shown that the local flow extends at least to $130 h^{-1} \text{ Mpc}$. However, in Refs. 32, 33 peculiar velocity fields were analyzed and found to be in agreement with a standard ΛCDM cosmology with no bulk flow, while in other work³⁴ an excess bulk flow was deduced. Moreover, there has little evidence of infall back toward the “Great Attractor” from material at larger distances. Although there is recent evidence³⁵ of a supercluster extending to a scale of $\sim 160 h^{-1} \text{ Mpc}$, there remains a need to search for evidence of a bulk flow at distances well beyond $\sim 160 h^{-1} \text{ Mpc}$. Indeed, a recent analysis³⁶ of the Cosmicflows-2 galaxy peculiar velocity catalog has confirmed a bulk flow of $250 \pm 21 \text{ km s}^{-1}$ out to a radius of $50 h^{-1} \text{ Mpc}$, and inferred a detectable bulk flow out to $200 h^{-1} \text{ Mpc}$.

It has been proposed^{37–41} that detecting such dark flow on cosmic scales may be possible by means of the kinetic Sunyaev-Zeldovich (kSZ) effect. This is a distortion of the CMB spectrum along the line of sight to a distant galaxy cluster due to the motion of the cluster with respect to the frame of the CMB. Indeed, a detailed analysis^{37–40} of the kSZ effect based upon the WMAP data⁶ seemed to indicate the existence of a large bulk flow velocity out to a distance of nearly $800 h^{-1} \text{ Mpc}$. However, this is an exceedingly difficult analysis,^{42, 43} and the existence of a dark flow has not been confirmed in a follow-up analysis⁴¹ using the higher resolution data from the *Planck* Surveyor. The *Planck* results set a (95% confidence level) upper limit of 254 km s^{-1} for the bulk flow velocity and are consistent with no dark flow. It has, however, been argued⁴⁴ that the background averaging method in the *Planck* Collaboration analysis may have led to an obscuration of the effect. Indeed, a subsequent analysis⁴⁵ of the combined WMAP and *Planck* data has suggested evidence of a dark flow. Nevertheless, the *Planck* Collaboration upper limit is still consistent with as much as half of the observed CMB dipole corresponding to a cosmic dark flow.

Independently of whether the dark flow has been detected via the kSZ effect, in view of the potential importance of this effect it is worthwhile to search for such

cosmic dark flow by other means.

An analysis of peculiar velocity fields is an alternative means to look for the effect of a dark flow. In particular, an analysis of the distance-velocity relationship (and more importantly its residuals) well beyond the scale of the Local Group is needed to identify a cosmic bulk flow. A number of attempts along this line have been made.^{33, 46–55}

For example, in Refs. 46, 47 the COMPOSITE sample of ≈ 4500 galaxies was utilized. For this set, distances were determined by the Tully-Fisher or “great plane” approach, plus a few by SN Ia distances. No dark flow was identified for distances greater than about $100 h^{-1}$ Mpc. However, this combined data set might have large systematic uncertainties from the distant objects. Hence, a more carefully selected data set was subsequently analyzed.⁴⁸ In that analysis the bulk flow magnitude was reduced to $\sim 300 \text{ km s}^{-1}$ and was only apparent out to about $80 h^{-1}$ Mpc.

Galaxies in which a SN Ia has occurred provide, perhaps, the best alternative^{49–55} because their distances are better determined. However there are fewer data available. There has been a wide variety in the attempts to find a bulk flow in SN Ia data sets. For example, Dai et al.,⁴⁹ utilized the Union2 data set from the Supernova Cosmology Project⁵⁶ and used a Markov Chain Monte Carlo (MCMC) search for the velocity and direction of the bulk flow. Colin et al.⁵¹ did the same but used a different maximum likelihood method. Weyant et al.⁵⁰ utilized a unique data set as described in their paper. They then used a weighted least squares and a coefficient unbiased method to find the coefficient of the spherical harmonics describing the cosmic expansion. Feindt et al.⁵³ analyzed data from the Union2 compilation combined with that from the Nearby Supernova Factory.⁵⁷ They added a coherent motion into their cosmological model to search for a dark flow.

The issue of sample sparseness has been considered in a number of works.^{50, 54, 55} Weyant et al.⁵⁰ found that biases appear due to a non-uniform distribution or if there is power beyond the maximum multipole in the regression. Rathaus et al.⁵⁴ also noted effects from large individual errors, poor sky coverage and the low redshift-volume-density, but they were still able to find a statistically significant bulk flow. Appleby et al.⁵⁵ found a bias in galactic latitude and attributed it to the lack of data in the region of $|b| < 20^\circ$.

Our study²⁹ differed from that of the previous analyses in several key aspects. We made an independent analysis based upon two different approaches and two separate data sets. We began with a slight improvement of previous searches^{49, 51, 53} based upon the Union2 data set by analyzing ~ 600 galaxies with SN Ia redshifts from the Union2.1 supernova data set.⁵⁸ We utilized a MCMC fit to the three Cartesian components of bulk flow velocity rather than the velocity magnitude in galactic coordinates. This approach had better stability near the Galactic pole. We then also analyzed the same data by searching for a deviation from Hubble flow with a $\cos\theta$ angular dependance on the sky. These studies established the robustness of these two complementary techniques for identifying the magnitude and direction of the bulk flow and confirmed previous detections of a bulk flow out to at least

$z = 0.05$.

Having established the viability of the methods adopted,²⁹ we then applied them for the first time to the large sample of (~ 1000) galactic redshifts and SN Ia distances from the *SDSS-II* survey.^{59,60} However, we found that the analysis of the *SDSS-II* data was severely limited by the paucity of data in the direction of the cosmic dipole moment. We establish²⁹ that there is a detectable bulk flow at low redshifts, but at best a marginal detection for high redshifts.

From simulated data sets, we deduced²⁹ that the current uncertainty at high redshifts arises mostly from the current error in the distance modulus. We estimated²⁹ that with a sample like the Union2.1 data set, a detection would require both significant sky coverage of SNIa out to $z = 0.3$ and a distance modulus error reduction from 0.2 to $\lesssim 0.02$ mag. However, a greatly expanded data set of 3×10^4 events might detect a bulk flow even with a typical distance modulus error of 0.2 mag as may be achievable with the next generation of large surveys like LSST.
